

RIVO MULTITRADE OPTICAL SYSTEMS

How often should relay protection be used

Overview

Protective relays should be tested as part of the full protection system, not just as standalone devices.

Key Takeaways

The optimal relay operating time is set to ensure the nearest relay to a fault operates first while upstream relays provide backup, typically achieved through time grading and proper TSM/PSM settings. Principles of Optimal Relay Timing

Time-graded protection is the most common method to achieve selective fault isolation. Relays closest to the fault are set to operate first, while upstream relays have progressively longer operating times to provide backup protection. This ensures that only the affected section is isolated, minimizing disruption to the rest of the network. Inverse time relays are often preferred in radial networks because their operating time decreases as fault current increases, allowing faster clearing for high-magnitude faults while maintaining selectivity for lower currents. Definite-time relays, in contrast, operate at a fixed delay regardless of fault magnitude.

Key Parameters

- Plug Setting Multiplier (PSM): Indicates how many times the actual current exceeds the relay pickup current. A higher PSM results in faster relay operation.

- Time Setting Multiplier (TSM): Scales the base operating time from the relay's characteristic curve. Lower TSM values produce faster tripping, while higher TSM values provide backup coordination .
 - Time Interval Between Relays: The difference in operating times between downstream and upstream relays must be sufficient to allow the downstream relay to clear the fault first, preventing unnecessary tripping of upstream devices .
- Coordination Procedure
- Conduct a load flow and short-circuit study to determine maximum and minimum fault currents and system impedances .
 - Set relay operating times to clear faults at maximum fault levels quickly while ensuring operation is satisfactory at minimum fault currents .
 - Plot relay and fuse curves on a common scale to verify selectivity and coordination .
 - Adjust TSM and PSM values to achieve the desired time grading, ensuring downstream relays trip faster than upstream relays .

Advanced Considerations

Modern systems may use optimization algorithms and adaptive relay settings to minimize total operating times while maintaining selectivity, especially in networks with distributed generation or bidirectional power flows . These approaches account for dynamic fault currents, network reconfigurations, and renewable integration.

Summary

The optimal relay time is a balance between fast fault clearance and selective coordination. Downstream relays should operate first, with upstream relays delayed just enough to provide backup. Proper use of inverse time characteristics, PSM, and TSM, combined with system studies and curve plotting, ensures reliable and efficient protection of the electrical network .
